## Abstract

Option-critic learning is a general-purpose reinforcement learning (RL) framework that aims to address the issue of long term credit assignment by leveraging temporal abstractions. However, when dealing with extended timescales, discounting future rewards can lead to incorrect credit assignments. In this work, we address this issue by extending the hierarchical option-critic policy gradient theorem for the average reward criterion. Our proposed framework aims to maximize the *long-term* reward obtained in the steady-state of the Markov chain defined by the agent's policy. Furthermore, we use an ordinary differential equation based approach for our convergence analysis and prove that the parameters of the intra-option policies, termination functions, and value functions, converge to their corresponding optimal values, with probability *one*. Finally, we illustrate the competitive advantage of learning options, in the average reward setting, on a grid-world environment with sparse rewards.

## Introduction

Humans routinely employ high-level temporal abstractions for everyday decision making. ? (?) investigate the use of learning temporally extended abstractions in order to augment the exploration and credit assignment capabilities of the actor-critic framework. However, employing a discount factor to bound the cumulative rewards can inadvertently lead to incorrect credit assignment. We address this issue by extending the framework proposed by ? (?) for the average reward (AR) criterion.

Figure 3(a) is a motivating example that illustrates how simple *traps* can beguile the discounted rewards (DR) framework into learning a sub-optimal credit assignment. It illustrates two different Markov chains, resulting from two disparate policies ( $\pi_R$  and  $\pi_B$ ).  $\pi_R$  always chooses red and  $\pi_B$  always chooses blue. When a DR-RL agent is at  $S_0$ , it has a predilection for the sub-optimal policy  $\pi_B$ , because  $\forall \gamma < 1$ :

$$v_{\pi_R}(S_{11}) = \frac{\gamma(2-\gamma)}{(1-\gamma^4)} < \frac{1}{(1-\gamma^4)} = v_{\pi_B}(S_{21})$$

## Policy-Gradient with Function Approximation

First, we illustrate how to extend the framework proposed by ? (?) for the AR criterion. Apart from addressing the AR criterion, our framework also presents a simplified and intuitive approach to dealing with hierarchical option-critic algorithms (?) by introducing the concept of  $o^0$  and  $o^N$ .

**Theorem 1** (Hierarchical Average Reward Option-Critic Policy Gradient (OCPG) Theorem). *Given an  $N$  level hierarchical set of Markov options with stochastic option policies at each level  $\pi^\ell$  and termination functions at each level  $\beta^\ell$  differentiable in their parameters  $\theta$ , the gradient of the expected reward per step with respect to  $\theta$  is:*

$$\begin{aligned} & \sum_{s, o^{0:N-1}, s'} \mu_\Omega(s, o^{0:N-1}, s') \left( \sum_a \frac{\partial \pi(a|s, o^{0:N-1})}{\partial \theta} \right. \\ & Q_U(s, o^{0:N-1}, a) + \sum_{o'^{0:N-1}} \sum_{\ell=1}^{N-1} \left[ \prod_{k=N-1}^{\ell} \beta^k(s', o'^{0:k}) \right. \\ & \frac{\partial \pi^\ell(o'^\ell | s', o'^{0:\ell-1})}{\partial \theta} Q_\Omega(s', o'^{0:\ell}) P_{\pi, \beta}(o'^{0:\ell-1} | s', o'^{0:\ell-1}) \\ & \left. \left. - \frac{\partial \beta^\ell(s', o'^{0:\ell})}{\partial \theta} A_\Omega(s', o'^{0:\ell}) \prod_{k=N-1}^{\ell+1} \beta^k(s', o'^{0:k}) \right] \right), \end{aligned}$$

**Figure 2:** An empirical demonstration illustrating the convergence of the parameters of  $Q(s, o)$ ,  $\pi(a|s, o)$ , and  $\pi(o|s)$ . We have randomly selected one parameter from each function approximator and plotted its value against the number of steps.

where  $\mu_\Omega$  is the stationary distribution of the Markov chain defined by the hierarchical policy, and  $P_{\pi, \beta}$  is the probability while at the next state, and terminating the options for the last state, that the agent arrives at a particular new set of option selections.

*Proof.* The proof for this theorem is in the Appendix.  $\square$

### Two-Timescale Convergence

Next, we prove that the aforementioned parameters,  $\theta$ , asymptotically converge to their optimal values, when employing a linear approximation  $\forall Q_\Omega$ . We analyze our framework using the ordinary differential equation (ODE) approach, delineated by ? (?), and study its asymptotic properties using the fixed points of the derived ODE.

**Theorem 2** (Convergence Proof). *For the parameter iterations of the global set of shared parameters defined in Algorithm 1, we have  $(\hat{J}_t, v_t, \theta_t) \rightarrow \{(J(\theta^*)_t, v^*, \theta^*) | \theta^* \in \mathcal{Z}\}$  as  $t \rightarrow \infty$  with probability one, where  $\mathcal{Z}$  corresponds to the set of local maxima of a performance function whose gradient is  $E[\delta_t^\pi \psi(s_t, a_t) | \theta]$*

*Proof.* The proof for this theorem is in the Appendix.  $\square$

### Empirical Results

Finally, we look at the susceptibility of our framework to traps, and compare it to the DR setting proposed by ? (?). Figure 3(b) depicts a grid world environment characterized by sparse rewards. An agent must navigate to either one of the pickup locations,  $P_1$  or  $P_2$ , in order to retrieve a parcel; and must subsequently deliver the parcel to the drop off location. The agent gets a reward of +100 for every parcel from  $P_2$ , and +50 for every parcel from  $P_1$ . The optimal policy for an agent would naturally involve picking up the parcels from  $P_2$ . We introduce a trap<sup>1</sup> at the green-blue junction to entice the DR-RL agents into picking up the parcels from  $P_1$ . Once the agent reaches the blue zone, it obtains a reward of +20 as opposed to a reward of +10 at the red-green

<sup>1</sup>The reward of +20 was primarily chosen for illustrating the potential pitfalls when employ a  $\gamma \leq 0.9$ . Similar traps can be created for any  $\gamma \leq 1$ .

**Figure 3:** (a) A trap that employs delayed rewards to fool DR-RL agents into learning incorrect credit assignments. (b) A grid-world navigation experiment where the reward at the drop off point depends upon which pickup location was previously visited (50 for  $P_1$  and 100 for  $P_2$ ). The trap at the blue-green junction misguides agents towards the sub-optimal pickup location,  $P_1$ .

junction. In Figure 1, we plot the rewards obtained per cycle for both the AR-RL agent and a DR-RL agent, and show that the hierarchical AR policy gradient performs better than its DR counterpart proposed by ? (?). Finally, we illustrate the asymptotic convergence of the actor and critic parameters in Figure 2.

### Conclusion and Future Work

In this work, we propose a novel method for maximizing the long term steady-state reward, by learning intra-option policies, termination functions, and value functions end-to-end. These algorithms can be used in infinite-horizon control problems that exhibit an inherent cyclic structure, like inventory-management, queuing and traffic light control. A detailed empirical analysis for a cyclical infinite-horizon application would be necessary to demonstrate the viability of our approach in complex environments. Additionally, while the proofs provided here leverage a linear approximation for each of the  $Q_\Omega(s, o^{0:\ell})$ , it would also be interesting to investigate the convergence properties of a non-linear critic.
